Introduction

Urinary ascites is an uncommon condition mainly associated with trauma or surgical induced urinary bladder perforation (1). It is known that polyuric syndromes, including psychogenic polydipsia and central or nephrogenic diabetes insipidus (NDI), may induce dilation of the urinary tract and rarely chronic renal damage (2, S1, S2, S3). We report the exceptional clinical case of a young man hospitalized for the study of progressive massive ascites following a lumbar trauma, who had a personal and familiar history of polyuria-polydipsia.

Case Presentation

A young male, 16 years old, was admitted to our hospital for the study of massive ascites, requiring an abdominal drainage puncture to alleviate pain and respiratory discomfort. About 4 months earlier, he had suffered lumbar trauma after a fall from a vehicle, followed by transitory macroscopic hematuria and slowly progressive abdominal distension. At admission, vital signs where normal, without facial or distal edema and no evidence of lumbar trauma. Laboratory testing revealed a normal hematological profile, a slight increase in serum creatinine (1.28 mg/dl), a very low urinary density (Table 1) and low urinary creatinine (7 mg/dl). A diagnostic/therapeutic drainage of ascites was performed, revealing a clear fluid, mild hypercellularity (300 mononuclear cells x mm³), creatinine concentration 3.26 mg/dl, without increases in triglycerides.

Imagenological studies (ultrasonography and computed contrasted tomography) revealed severe bilateral hydroureteronephrosis without evidence of obstructive factors, but signs of old fractures on 11° and 12° left ribs, massive ascites and a left perirenal collection that was filled by leakage of contrast media from the renal pelvis (Figure 1)
After several therapeutic paracentesis, ascites reproduced rapidly whilst the patient remained intensely polyuric (urinary output 22 lts/day). He recognized a long-lasting history of polyuria and polydipsia, since he could remember, having suffered school bullying because frequent urination and enuresis. The polyuria-polydipsia condition was shared by many members of his maternal family (Figure 2). No history of treatments or drugs was obtained. A cystoscopy was performed, ruling out obstructions or lesions at the low urinary tract, although a distended and trabeculated bladder was observed. A pyelo-vesical pig tail at the left side and a Foley catheter were inserted, with rapid resolution of the ascites, although maintaining a small perirenal collection at ultrasonography. All microbiological cultures of ascites fluid were negative, including mycobacteria. Once the patient was stable, he was submitted to a short (7 hours) water deprivation test, without changes in urinary volume (700 ml/h) nor increase in urinary density (starting with 1.003 and ending with 1.002), but an increase in natremia to 154 meq/lt. No response was obtained after arginine vasopressin administration (2 nasal puffs after the test and 1 tablet every 12 hours in the following 2 days), remaining with polyuria and polydipsia but ascites did not recur. An empiric treatment with oral hydrochlorothiazide failed, without changes in urinary volume and we decided not to try with indomethacin.

A genetic analysis by direct sequencing of all the AVPR2 and AQP2 coding-exons identified a hemizygous variant in AVPR2, c.604C>T (p.R202C), predicted to be pathogenic (3). His mother, with a long history of polydipsia and polyuria of 7 liters/day, is a heterozygous carrier for the same variant.
Discussion

This exceptional case illustrates the unusual diagnosis of a familiar nephrogenic diabetes insipidus after a traumatic injury of a severely dilated urinary tract in a young man.

The high rurality, early beginning of the polyuric syndrome and coexistence of relatives with the same condition, may explain the diagnostic delay. During school the patient had to retain voluntarily very high urine volumes that may have caused the massive chronic bladder distention, with secondary vesicoureteral reflux.

The study of the ascites fluid suggested a urinary origin because its creatinine concentrations were higher than the serum but lower than the urinary, although it was under the normal values due to the very diluted urine. Edema was not found in other sites of the body and no evidence of liver or other renal disease as causes of the ascites where demonstrated. An infection of peritoneal space was also discarded by cultures and the mild increase in mononuclear cells was attributed to sterile irritation of the peritoneum by the presence of urine.

Urinary ascites associated to traumatic or surgical injury of the urinary bladder has been reported (1, S4). In our patient, one of the fractured ribs, may have penetrated the retroperitoneal space during the trauma, wounding a dilated pelvis and creating a small communication between the retroperitoneal and peritoneal space, causing the massive ascites facilitated by the enormous urinary volumes. Only one similar case has been reported, but the cause of the urinary tract damage could not be identified (4). We are confident on the injury mechanism proposed in our patient because scan showed contrast leakage from the renal pelvis to retroperitoneum in the vicinity of a rib fracture, and ascites resolved after the isolation of the urine fistulae with a pig tail insertion. On the other hand, the beginning of polyuria at childhood, the absence of drugs or other medical conditions and the existence of affected relatives in the mother’s family, suggested a rare inherited condition characterized by a kidney insensitivity to arginine vasopressin with the
consequent inability to concentrate the urine: Hereditary NDI. This condition has been described in an X-linked form in association with variants in the gene encoding the vasopressin receptor-2 (AVPR2) or an autosomal form due to genetic variants in the water channel aquaporin 2 (AQP2), both inherited in a recessive fashion, although dominant forms have been reported (S5). About 90% of the patients carry variants in AVPR2, and more than 250 mutations have been described until today (5).

The AVPR2 variant carried by our patient and shared by his mother has been described previously in persons with moderate-severe NDI phenotype (3, S6); functional in vitro assays have demonstrated that this variant has normal expression and reaches the cell surface without impacting the mRNA expression, but ligand binding activity is significantly reduced in comparison to the normal protein (6). Altogether, missense variants represent more than half of the NDI cases. Arginine to cysteine is the most common amino acid substitution in AVPR2 and arginine the amino acid with the highest mutability rate more likely to cause a clinical disease (7).

Since vasopressin receptor genes are in the X chromosome, it is important to highlight that polyuric syndromes may be observed in women carrying these variants. However, the random X chromosome inactivation produces a capricious degree of phenotypic expression (5).

As with most rare diseases, little long-term clinical data exists to inform management and prognosis. Previous reports have highlighted the potential complications of flow uropathy and behavioral abnormalities, such as attention deficit disorders and severe psychomotor delay, sometimes associated with intracranial calcifications (8). New treatment approaches for congenital NDI have been tested in animal models, but efficacy in patients has not yet been confirmed (9, S7, S8).

Physicians should be encouraged to follow up families with suspected X-linked NDI and to consider early genetic testing of symptomatic relatives, (pre)symptomatic females or at-risk male infants to
prevent dehydration associated with significant morbidity and mortality, advice about double
voiding to reduce further dilation of the urinary tract and perform regular ultrasound surveillance.

The main teaching messages are shown in Table 2.
