The Density of Renal Lymphatics Correlates with Clinical Outcomes in IgA Nephropathy

RETROSPECTIVE STUDY
- Multicenter (Spain)
- IgA Nephropathy
  - n=76
- PRIMARY ENDPOINT
  - Progression to ESKD

Aim: To establish the prognostic value of the density of lymphatic vessels in the kidney biopsy at the time of diagnosis for predicting the risk of ESKD in a Spanish cohort of patients with IgAN

Associations with higher density of lymphatic vessels
- Mesangial Hypercellularity ≥50%
- Segmental sclerosis
- Higher degrees of interstitial fibrosis and tubular atrophy
- Higher levels of proteinuria
- Lower eGFR

A density of lymphatic vessels ≥ 8 per mm² was associated with a significantly higher rate of progression to ESKD at 3 years from biopsy

Conclusion
This study contributes to the understanding of the natural history of the progression to ESKD in IgAN patients showing that the density of lymphatics vessels may optimize the prognostic value of the international IgA predicting tool to calculate the risk of ESKD, favoring the evaluation of new targeted therapies.

Running head: Lymphangiogenesis in IgA nephropathy
ABSTRACT

Background and objectives: IgA nephropathy (IgAN) is the most common primary glomerulonephritis worldwide. The disease course fluctuates, and the most important challenge is the considerable variation in the time lag between diagnosis and the development of a hard clinical endpoint such as end-stage kidney disease (ESKD). The reaction of renal tissue to damage resembles the common wound-healing response. One part of this repair in IgAN is the expansion of lymphatic vessels known as lymphangiogenesis. The aim of this work was to establish the prognostic value of the density of lymphatic vessels in the renal biopsy at the time of diagnosis, for predicting the risk of ESKD in a Spanish cohort of patients with IgAN.

Methods: We performed a retrospective multicenter study of seventy-six patients with IgAN. The study’s endpoint was progression to ESKD. The morphometric analysis of lymphatic vessels was performed on tissue sections stained with anti-podoplanin antibody.

Results: Density of lymphatic vessels was significantly higher in IgAN patients with mesangial hypercellularity > 50%, segmental sclerosis, higher degrees of interstitial fibrosis and tubular atrophy. Patients with more lymphatic vessels had significantly higher values of proteinuria and lower estimated glomerular filtration rate (eGFR). A density of lymphatic vessels ≥ 8 per mm² was associated with a significantly higher rate of progression to ESKD at 3 years from biopsy. After adjustment for the International IgAN prediction score, at the multivariate logistic regression, high density of lymphatic vessels (≥ 8 per mm²) remained significantly associated with a higher rate of early progression to ESKD.

Conclusions: This study contributes to the understanding of the natural history of the progression to ESKD in IgAN patients showing that the density of lymphatics vessels may optimize the prognostic value of the international IgA predicting tool to calculate the risk of ESKD, favoring the evaluation of new targeted therapies.
Background

IgA nephropathy (IgAN) is the most common primary glomerulonephritis (GN) worldwide. The incidence rate has been estimated at 2–10 per 100,000 person-years. A renal biopsy with mesangial deposition of IgA immune complex is required for diagnosis. (1) The disease course is very variable because of its clinical, pathological, and pathogenic heterogeneity; and ranges from asymptomatic non-progressive to aggressive, with up to one in four patients suffering from end-stage kidney disease (ESKD) within 20 years from diagnosis. (2)

Several retrospective studies have identified hypertension, renal function at diagnosis, and the magnitude of proteinuria during follow-up as the most important clinical predictors of ESKD. Of them, a sustained protein excretion above 1 g/d is considered as the most determinant predictor of progression, and treatment recommendations are based on the magnitude of proteinuria. (3) More recently, some studies have shown that histological lesions included in the Oxford Classification are independently associated with renal outcomes and significantly improve the prediction of disease progression to ESKD. (4)

The final pathway to chronic kidney disease (CKD) and kidney failure is always the loss of normal tissue and matrix deposition with fibrosis in every kidney compartment. The extent of renal fibrosis predicts the loss of function and progression of damage in the kidney. Thus, renal biopsy is not only useful for diagnosis and prognostic categorization, but it can also quantify fibrosis and elucidate new therapeutic targets that could prevent the progression of IgAN. (5)

The reaction of renal tissue to damage resembles the common wound-healing response that occurs in other tissues. However, the repair and recovery of renal function do not always happen. One part of this repair in IgAN is the expansion of lymphatic vessels known as lymphangiogenesis; as well as functional changes in lymphatic vessel morphology, lymphangiogenesis occurs in response to numerous noxious stimuli including interstitial fluid overload and inflammation. Thus, determination of how to target lymphatic vessels may have impact in the treatment and prevention of chronic kidney disease. (6)

Adequate categorization of patients in individual risk classification for ESKD in IgAN is an essential aspect when making therapeutic decisions and designing clinical trials. The most important challenge is the considerable variation in the time lag between diagnosis and the development of a hard clinical endpoint such as ESKD. (7) Previous immunohistochemical studies of lymphatics with anti-podoplanin antibody have elucidated their relation to the overall anatomical structure of the normal human kidney and in ESKD, cortical infarction, acute tubular necrosis, and hydronephrosis; the use of podoplanin antibody for the detection of renal lymphatics is well characterized under both normal and pathological conditions and the distribution patterns of lymphatics are like those previously reported in animals. (8)

The aim of this work was to establish the prognostic value of the density of lymphatic vessels in the renal biopsy at the time of diagnosis to predict the risk of ESKD in a Spanish multicentric cohort of patients with IgAN that was followed for a prolonged period with periodic visits, in which all recognized clinical and laboratory risk factors for disease progression were systematically recorded.
In this way, we were able to consistently analyze the correlation of lymphangiogenesis with the appearance of renal fibrosis in the biopsy and its correlation with disease progression.

**Materials and methods**

**Study population**

This study was designed to include all consecutive patients with biopsy proven IgAN and followed up from January 2012 to December 2018 in 5 nephrology departments belonging to the Catalan Group for the Study of Glomerular Diseases (GLOMCAT). Patients with other underlying autoimmune diseases or hepatitis B or C infection were excluded from further consideration.

The diagnosis of IgAN was based on the Oxford classification criteria on native kidneys (9). Biopsies with fewer than ten glomeruli were excluded to assure a representative sample. All data were retrospectively collected from the time of IgAN diagnosis until December 2020. All patients gave written informed consent. The study was approved by the institutional review board of the Hospital Clinic of Barcelona and was conducted in accordance with the Declaration of Helsinki.

**Histological characterization**

All biopsies were processed for light and immunofluorescence microscopy using standard techniques, examined by an experienced nephropathologist, and interpreted according to the Oxford Classification of IgAN.

The morphometric analysis of lymphatic vessels was performed on formalin-fixed, paraffin-embedded tissue sections using BenchMark ULTRA (Ventana) and commercially available antibody (podoplanin: D2-40, mouse monoclonal antibody, ready to use, CELL MARQUE). The D2-40 antibody was used after standard antigen retrieval (CC1 solution Ventana; 36 min, 95°C).

Podoplanin is a ~38 kD O-linked transmembrane sialoglycoprotein expressed on the endothelium of lymphatic capillaries, but not in the blood vasculature. Clone D2-40 recognize podoplanin in normal and neoplastic tissues, and it has been used for the identification of lymphatic invasion in a variety of cancers. (10-11)

Lymphatic vessels were counted only in the cortex, and their areas were measured, using an Olympus Cell B Basic Imaging Software and the Olympus SC50 camera attached to an BX51 microscope. Lymphatic areas were defined as vascular areas delineated by D2-40 positive staining. Evaluated parameters included microvessel areas, the total area of the biopsy analyzed, the density of lymphatic vessels (number per mm² biopsy area) and the proportion of the examined area occupied by lymphatic vessels.

**Clinical data**

The following data were retrieved from the medical records of the patients: demographic data and concomitant medical conditions, both at presentation and follow-up (3, 6, 12, 24, 60 and 120 months or last outpatient clinic visit); time to last visit, and time to the main follow-up landmarks (remission, progression to ESKD, death), as well as information on treatment (corticosteroid, other immunosuppressive drugs, renin-angiotensin [RAS] system blockers). Laboratory tests at presentation and during follow-up were also retrieved: blood cell counts, serum creatinine, eGFR measured with CKD-EPI, serum albumin, 24-hour proteinuria, urinary sediment and albumin.
International IgAN prediction tool

The International IgAN Prediction Tool in adults was used to calculate the risk of 50% decline in eGFR or progression to end-stage renal disease at 5 years after renal biopsy. The risk equations were derived in a multi-ethnic international cohort of 2781 patients with biopsy proven idiopathic IgA nephropathy. (12)

Renal survival

The main study’s endpoint was progression to ESKD, defined as an eGFR <15 ml/min/1.73 m2, the need for dialysis or preemptive kidney transplantation.

Statistical analysis

Continuous variables were summarized as mean and standard deviation or median and interquartile range (IQR). Categorical variables were described by proportions and compared using the chi-square test or the Fisher test when applicable. Comparisons between groups were made using the t-test for two independent samples and the Mann-Whitney test for non-normal samples. Kaplan-Meier estimates were used for renal survival by IFTA. The association between progression to ESKD at the 3-year landmark and either density of lymphatic vessels or the Oxford MEST score was evaluated by multivariable logistic regression and expressed as odd ratio (OR) and its 95% confidence interval (CI). Statistical analyses were performed with Stata software, version 11, (www stata.com), and GraphPad Prism, version 7.0 (GraphPad Software, USA). The significance level was fixed at 0.05.

Results

Baseline clinical characteristics

A total of 125 IgAN patients were retrieved from our records, of whom forty-nine cases were excluded due to non-fulfillment of inclusion criteria or because of missing data (criteria were very strict to ensure the quality of the data of this proof concept study). Seventy-six patients were finally included in the analysis. The mean age was 41 years (30-49 years), 68 were Caucasians and 8 Asiatic, and 48 were males (74%). At presentation, 25 (33%) patients had arterial hypertension, the mean proteinuria was 1.3 g/d, 68 (89%) were on treatment with RAS blockade agents, and 16 (21%) were receiving corticosteroids.

Correlation between the density of lymphatic vessels and other histopathological features

The median density of lymphatic vessels per mm² of biopsy was 2.8 (IQR: 1.0-5.5) and occupied a median of 0.4% (IQR: 0.2-0.7) of the examined area. There was a strong correlation between density and area of lymphatic vessels (R²=0.87, p< 0.001; supplementary figure S1). Figure 1 shows photomicrographs of renal biopsies stained with D2-40 (lymphatic vessels).
Table 1 summarizes the correlation between density of lymphatic vessels and other histopathological features. The density of lymphatic vessels was significantly higher in patients with mesangial hypercellularity (MH) > 50%, segmental sclerosis, and higher degrees of interstitial fibrosis / tubular atrophy.

To further investigate the clinical and prognostic features associated with the density of lymphatic vessels, we categorized density as ≥ 8 vessels per mm² (n=11) or lower (n=65). We relied on receiver operating characteristics (ROC) curve analysis to select the optimum density value around the 0.75 percentile (Supplementary figure S2).

Clinical characteristics at the time of renal biopsy according to the density of lymphatic vessels

Table 2 summarizes the main clinical characteristics at the time of renal biopsy according to the density of lymphatic vessels. Patients with more lymphatic vessels had significantly higher values of proteinuria and lower eGFR. There were no significant differences between both groups in the incidence of comorbidities or microscopic hematuria.

Clinical outcomes according to the density of lymphatic vessels

After a median follow-up of 2.5 years (IQR: 1.1-3.3), twelve patients had progressed to ESKD, and three patients had died (2 in ESKD). Median survival was not achieved and the estimated survival at 6 years from the biopsy was 90% (95% CI: 73-97).

A density of lymphatic vessels ≥ 8 per mm² was associated with a significantly higher rate of progression to ESKD (log-rank test p=0.01; figure 2). At 3 years from biopsy, the progression rate to ESKD was 7% in patients with density values < 8 per mm² versus 53% in patients with values ≥ 8 per mm².

Correlation between density of lymphatic vessels and the International IgAN prediction score

In the whole series of seventy-six patients with IgA nephropathy, the prediction score ranged from 0.18 to 60.0 with a median of 8.8. Patients with a high density of lymphatic vessels (≥ 8 per mm²) scored significantly higher (median: 25.7, IQR: 11.2 - 34.9) than patients with lower density (median: 6.0, IQR: 2.6 - 15.3; p=0.003, Figure 3).

The density of lymphatic vessels and International IgAN prediction score as predictors of progression to ESKD

Based on the profile of progression to ESKD shown in figure 2, we investigated whether a high density of lymphatic vessels can refine the prognostic significance of the international score to predict early progression to ESKD. After excluding patients who did not progress and were followed by less than 3 years, both the score (OR 1.12, 95% CI 1.03-1.22; p=0.008) and density of lymphatics ≥ 8 per mm² (OR 26, 95% CI 3.4-195; p=0.002) were individually associated with a higher risk of progression within the first 3 years of follow-up. At the multivariable logistic regression, high density of lymphatic vessels (≥ 8 per mm²) remained significantly associated with a higher rate of early progression to ESKD (OR 10.5, 95% CI 1.1-96.6; p=0.03), even after adjustment for the score (OR 1.0, 95% CI 0.9-1.2; p=0.05).
Discussion

Herein, we describe the clinical characteristics, outcomes, and the relation of renal lymphangiogenesis with the progression of the disease of an observational cohort of patients with IgAN. There are several major findings in this study. First, the density of lymphatic vessels was significantly higher in IgAN patients with mesangial hypercellularity (MH) > 50%, segmental sclerosis, higher degrees of interstitial fibrosis and tubular atrophy. Second, patients with more lymphatic vessels had significantly greater values of proteinuria and lower eGFR. Third, the density of lymphatic vessels ≥ 8 per mm² was associated with a significantly higher rate of progression to ESKD at 3 years from biopsy. Finally, after adjustment for the International IgAN prediction score, at the multivariate logistic regression, high density of lymphatic vessels (≥ 8 per mm²) remained significantly associated with a higher rate of early progression to ESKD.

It is not known with certainty if there is a point of no return in IgAN, but most studies suggest that progression to ESKD is inexorable once the eGFR falls below 20-30 mL/ min / 1.73 m² in the presence of advanced chronic changes in the renal biopsy. (13-14) Establishing a reliable chronicity index that stratifies the appearance of interstitial fibrosis and tubular atrophy from preliminary stages is an urgent need in this complex glomerular disease. (15) The field of risk stratification in IgAN has been optimized by the recent validation of a new international risk-prediction tool in large, multiethnic cohorts from the International IgA Network. This tool can predict the kidney-specific endpoints of a 50% decline in kidney function or ESKD with a quite reasonable accuracy in large cohorts but the utility at the individual patient level has yet to be confirmed in the long term. (16)

Structural changes to the vasculature are a prominent feature of CKD. Whereas peritubular capillaries undergo rarefaction, potentially triggering interstitial hypoxia and generating a profibrogenic environment within diseased kidney (17); renal lymphatics proliferate and sprout, giving rise to new vessels in a process termed lymphangiogenesis.(18) It has been previously described in murine models of CKD and in clinical cases of IgAN, focal glomerulosclerosis, lupus nephritis, ANCA-related GN, diabetic kidney disease and chronic interstitial nephritis, with disease ranging from moderate CKD to ESKD, that the cross-sectional area of lymphatics was significantly greater than in non-diseased kidneys.(19-20-21).

The results reported here, not only confirmed these preliminary observations in a whole cohort of patients with IgAN if not, they represent, to the best of our knowledge, the first study that identifies a cut-off point of 8 lymphatic vessels / mm² as a risk factor for rapid progression to ESKD, indicating that the density of lymphatic vessels in the renal biopsy of IgAN patients may become a new surrogate marker to optimize the personalized stratification of chronic damage and the risk of progression to ESKD. Moreover, using the international risk score, with the predictive values of the Oxford subgrouping and lymphatic density, we found a higher risk of progression at 3 years, being an additional tool for making therapeutic decisions at the time of diagnosis of IgAN.
From our point of view, conducting this proof-of-concept study in IgAN was a priority because it is the most common primary glomerular disease. However, soon it may be used in the study of CKD associated with other nephropathies because higher lymphatic density may be a common pathway, seen in kidney fibrosis.

Unfortunately, we still do not have any specific treatment for patients diagnosed with IgAN, after deposition of IgA1-containing circulating immune complexes there is an inflammatory response characterized by the infiltration of immune cells with the objective of controlling the damage and recovering tissue functionality. However, as nephron endowment is limited, and kidneys are unable to generate new nephrons, ongoing inflammation or repeated episodes of kidney injury will lead to further nephron loss that is associated with the development of cell senescence and kidney fibrosis. (22)

Currently, evidence has confirmed that the clinical parameters of poor prognosis in IgAN, have a lower weight when histological lesions are well characterized.(23) The density of lymphatics vessels may also be evaluated in the near future in follow-up biopsies to establish its potential role as a marker of treatment response, evaluating the ability to halt the progression of renal fibrosis of classic drugs such as blockers of the renin-angiotensin-aldosterone axis and of new molecules such as SGLT2 inhibitors (SGLT2-i). Due to the recent published pre-specified analysis of the DAPA-CKD trial, that demonstrated the effects of dapagliflozin on major adverse kidney events in patients with IgAN, it will also be especially attractive to analyze the role of SGLT2-i due to its multiple renal effects, not only avoiding proteinuria due to hemodynamic effect (control of glomerular hypertension) but also affecting metabolic stress and inflammation, thus breaking the vicious circle: inflammation, fibrosis, and lymphangiogenesis. (24)

Recently, the TESTING study showed that patients with IgAN and proteinuria > 1 g/d can benefit from long-term use of corticosteroids in nuanced doses. Adding new predictive markers for ESKD, such as density of lymphatics vessels, is of great relevance to better characterize the group of patients in whom the risk of exposure to steroids is well balanced with respect to the clinical benefit. (25)

This highlights the importance of renal biopsy not only for diagnosis, but also to enable individualized treatment to be administered to patients with IgAN.

From another point of view, the kidney contains a network of lymphatic vessels that clear fluid, small molecules, and cells from the renal interstitium and are implicated in renal disease, but their function in inflammatory kidney diseases, such as IgAN, is poorly defined. Studies of lymphangiogenesis in development (26) or pathology have identified a plethora of growth factors that promote or inhibit lymphatic vessel growth. Of those studied in the kidney, VEGF-C and VEGF-D are central for lymphangiogenesis in renal disease. These growth factors predominantly trigger lymphangiogenesis by activation of VEGFR-3, but VEGF-C can also act via VEGFR-2 to stimulate Lymphatic Endothelial Cells and blood vessel proliferation and migration (27). VEGF-C is highly expressed by macrophages in the rat remnant kidney, (28) murine unilateral ureteral obstruction, human biopsies of IgAN, DKO36 and chronic allograft rejection (29).

Thus, to determine how to target lymphatic vessels may have an impact in the treatment and prevention of chronic kidney disease in IgAN. Structural changes to renal lymphatics are not evident in murine or human AKI. However, the possibility that renal lymphatics are altered at the molecular or functional level in acute nephropathy, and whether these can be exploited to prevent the transition from AKI to CKD, warrants further study. The mechanisms of action of pro- or anti-lymphangiogenic factors to prevent fibrotic remodeling in preclinical models of CKD, whether through clearing inflammatory cells, modulating factors secreted by Lymphatic endothelial cell, effects on the blood vasculature through VEGFR-2 activation, or consequences on other cells in the fibrotic environments are yet to be elucidated.

Kasinath et al. (30) have examined the role of the kidney draining lymph node in experimental GN, as well the role of
fibroblastic reticular cells within lymph nodes. Removing the kidney-draining lymph nodes prior to the induction of GN attenuated disease, as did interventions that affected the function of lymph nodes in general.

In IgAN, tubular atrophy and interstitial fibrosis may be induced by filtration of proteins to the tubular lumen, and enhanced tubular reabsorption of proteins induces synthesis of pro-inflammatory and profibrotic factors, which drive kidney damage. Lymphatics in these areas might function to drain the misdirected filtrated fluid into the tubulointerstitial area and, in animal models; the distribution of lymphatic vessels was restricted around the affected nephron. Moreover, misdirected tubular fluid filtration into the periglomerular space appears to enhance periglomerular fibrosis and lymphangiogenesis. (32-33)

Some limitations should be acknowledged. First, due to the observational and retrospective nature of the study, no causal relationships can be established. Second, treatment-related adverse events were not collected. Third the absence of a replication cohort. Despite these limitations, this study further contributes to the understanding of the natural history of the progression to CKD in IgAN patients showing that the density of lymphatics vessels may optimize the prognostic value of the international IgA predicting tool to calculate the risk of ESKD at 3 years. Prospective studies, that ideally include control biopsy, are warranted to confirm these findings.

In conclusion, patients with a higher density of lymphatics (≥ 8 per mm2) progress faster to ESKD and this effect of early progression is maintained after adjusting for the IgAN international score. This study identifies new surrogate measures of kidney outcomes and open new ways for the improvement ESKD prediction of patients with IgAN. This may decrease the cost and complexity of clinical trials in IgAN, thereby favoring the evaluation of new therapies.
